## Abstract

Nitrogen-containing stainless steel was prepared by a novel combination of plasma nitriding and solid solution. The performance of the treated samples was evaluated by X-ray diffraction (XRD), micro-hardness test and electrochemical polarization. The results showed that a thick nitrogen-containing layer composed of nitrogen expanded austenite ( $\gamma\text{N}$ ) layer was obtained by the novel technology, and the corresponding  $\gamma\text{N}$  peaks appeared at lower angles comparing with those of the untreated sample. Meanwhile, both the microhardness and corrosion resistance were enhanced in comparison with those of the untreated sample.

## Keywords

Nitrogen-containing, Austenitic stainless steel, Plasma nitriding, Solid solution treatment

## Introduction

As was reported that the hardness and strength of austenitic stainless steel can be significantly improved with the addition nitrogen and the corrosion resistance can be further enhanced as well [1-4]. The existed methods to produce nitrogen-containing austenitic steel include high pressure melting and high temperature gas nitriding etc. [5-8]. Unfortunately, these methods are hard to be carried out in practical applications; especially they are restricted by the demand of special equipments. Therefore, it is of significant value to develop a new method to prepare nitrogen alloyed stainless steels.

Plasma nitriding is a kind of chemical heat treatment technology, during which the nitrogen atoms can diffuse into the metals by ion sputtering to form nitriding layer with much higher nitriding efficiency comparing with most other existing nitriding technologies [9-11]. Unfortunately, plasma nitriding of austenitic stainless steel is usually accompanied with the precipitation of chromium nitrides, which brings out the deterioration of the corrosion resistance due to the depletion of the chromium content in the matrix. Though a single S-phase without chromium nitrides precipitation in the nitriding layer can be formed at temperatures lower than 450 °C, the rate of plasma nitriding process is very slow at this low temperature, leading to very long duration for getting deep nitriding layer, which results

in very low production efficiency and high cost in real application [12,13].

Solid solution is a kind of heat treatment by heating the treated metal to high temperature and holding for enough time for fully decomposing the compounds existed in the matrix, and then rapidly cooling to get a supersaturated solid solution [14].

Based on the characteristics of both plasma nitriding and solid solution, a novel complex treatment of plasma nitriding and solid solution was developed, and the research goal is to obtain deep nitrogen-containing layer by this complex treatment and evaluate the performance of the nitrogen-containing stainless steel.

## Experimental Procedures

The material used in this research was 304 austenitic stainless steel with the following chemical compositions (wt. %): 0.07C, 1.00Si, 2.00Mn, 18.15 Cr, 8.5 Ni, and Fe balance. The initial specimens were machined into the size of 10 mm × 10 mm × 5 mm. All the surfaces of specimens were treated by using silicon carbide emery papers of different granulometry to achieve a fine finish, and ultrasonically cleaned in dehydrated ethanol for 10 min and dried before plasma nitriding.

Plasma nitriding treatment (referred to as PN) was conducted in a type LD-8CL D.C. plasma nitriding unit with a 24% N<sub>2</sub> + 76% H<sub>2</sub> atmosphere and gas pressure of 400 Pa at 560 °C for 8 h, then the nitrided samples were treated by solid solution (referred to as SS) at 1050 °C for 10 h, followed by water quenching.

The phase constituents were determined by X-ray diffraction (XRD) with Cu-Kα ( $\lambda/4$  1.54 Å) radiation with scan rate of 0.2°/min, 2θ ranging from 20° to 90°. Hardness measurements were measured by HXD-1000TMC micro-hardness tester with the test load of 25 g and the holding duration of 15 s. Corrosion behavior was evaluated by the potentiodynamic polarization curves in 3.5% NaCl aerated solution using ZAHNER IM6e electrochemical workstations.

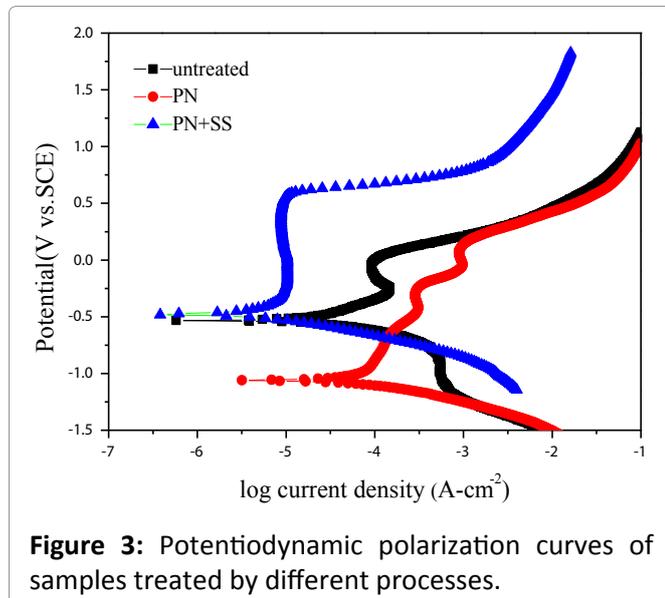

## Results and Discussions

### XRD analysis

Figure 1 shows the XRD patterns of samples untreated and treated by different processes. It clearly illustrates that only typical peaks corresponding to  $\gamma$  phase exist for untreated sample, and the phase compositions are consisted of  $\epsilon$ -Fe<sub>2,3</sub>N,  $\gamma'$ -Fe<sub>4</sub>N and CrN for plasma nitriding (PN) sample, while only typical peaks corresponding to  $\gamma$ N phase exist for PN+SS sample. Therefore, it can be concluded that the nitrides formed during PN process are decomposed by the subsequent solid solution treatment. And the embedded Figure 1 presents that  $\gamma$ N has lower diffraction angles than those of  $\gamma$  for the untreated sample.

### Micro-hardness analysis and tribological behavior

Figure 2 shows the micro-hardness profile of samples untreated and treated by the complex process. It can be seen that the PN+SS sample owns higher surface hardness and deep effective hardening layer. The surface hardness of the speci-

men treated by PT+SS is 295 HV0.025, improved 85 HV0.025 compared with that of untreated sample. Meanwhile, the effective hardening layer of the specimen treated by PT+SS reaches 1.1 mm. The increase in hardness could be attributed to the formation of  $\gamma\text{N}$  phase as shown in Figure 1, which is a supersaturated solid solution of nitrogen in the austenite, hardness improvement by solid solution strengthening by nitrogen atoms.

### Corrosion behavior

Figure 3 shows the potentiodynamic polarization curves of samples treated by different processes. It is obvious that the PN+SS sample owns the highest corrosion potential, with higher corrosion potential of  $-0.473\text{ V}$  and lower corrosion current of  $1.045 \times 10^{-6}\text{ A/cm}^2$ . The polarization curve of the PN+SS sample illustrates that the passive behavior due to the formation of the nitrogen expanded austenite ( $\gamma\text{N}$ ), the incorporation of nitrogen in the interstitial position of the austenite can improved the pitting corrosion resistance of deep nitriding austenitic stainless steel.

### Discussion

From the above results, it can be concluded that deep nitrogen-containing layer of stainless steel was formed by the novel combination of plasma nitriding and solid solution. The first step of plasma nitriding is used to get high content of nitrogen in the surface layer of austenitic stainless steel, and solid solution is used to fully decompose the chromium nitrides formed during plasma nitriding and let nitrogen atoms dissolve into the matrix,

and thus nitrogen-containing stainless steel can be prepared.

XRD patterns shows that  $\gamma\text{N}$  has lower diffraction angles than those of  $\gamma$  for the untreated sample due to nitrogen atoms dissolving in the interstitial position of the face centered cubic (fcc) austenite, thus bringing out the shift towards lower angles according to the Bragg Law.

As was known that the addition of nitrogen can improve the hardness of austenitic stainless steel through solution strengthening of interstitial nitrogen, and the corrosion resistance can also be enhanced due to the increase of passive film's stability by the addition of nitrogen [14], therefore, higher hardness and better corrosion resistance were obtained for the prepared nitrogen-containing stainless steel.

### Conclusions

1. Austenitic stainless steel with deep nitrogen-containing layer was prepared by a novel complex treatment of plasma nitriding and solid solution combination.
2. The deep nitrogen-containing layer was composed of nitrogen expanded austenite ( $\gamma\text{N}$ ) layer, and  $\gamma\text{N}$  has lower diffraction angles than those of  $\gamma$  for the untreated sample.
3. The austenitic stainless steel with deep nitrogen-containing layer has higher hardness and better corrosion resistance, with higher corrosion potential and lower current density in comparison with those of the as-received sample.
